Abstract—Numerical calculations with finite-difference time-domain (FDTD) on metallic nanostructures in a broad optical spectrum require an accurate approximation of the permittivity of dispersive materials. Here, we present the algorithms behind B-CALM (Belgium-California Light Machine), an open-source 3D-FDTD solver operating on Graphical Processing Units (GPU’s) with multi-pole dispersion models. Our modified architecture shows a reduction in computational times for multi-pole dispersion models for a broad spectral range. We benchmark B-CALM by computing the absorption efficiency of a metallic nanosphere and compare it with Mie theory. We present an algorithm to simulate multi-pole Drude-Lorentz materials and minimize thread divergence, enabling fast simulations of complex materials. As an example, we use B-CALM to simulate the absorption cross section of a gold nanosphere and compare the results with Mie theory. We find that a multi-pole Drude-Lorentz model significantly improves numerical accuracy.

I. INTRODUCTION

Finite-Difference Time-Domain (FDTD) simulations play a prominent role in numerical electromagnetic calculations\cite{1}. Many problems in nanophotonics require three dimensional full-field simulations, and FDTD simulations are often limited by the available computational power. While GPU’s can be used as a very low cost hardware solution to accelerate FDTD, dispersive materials have been implemented for microwave frequencies, where the material dispersion can be simply modeled as a one-pole Drude medium\cite{2}. However, metals at optical frequencies can have a permittivity with more complex features, which requires including multiple resonances to obtain an accurate model\cite{3}. We present an algorithm to simulate multi-pole Drude-Lorentz materials and minimize thread divergence, enabling fast simulations of complex materials. As an example, we use B-CALM to simulate the absorption cross section of a gold nanosphere and compare the results with Mie theory. We find that a multi-pole Drude-Lorentz model significantly improves numerical accuracy.

II. DRUDE-LORENTZ MODEL FOR DISPERSIVE MEDIA

The complex permittivity $\epsilon(\omega) = \epsilon' + i\epsilon''$ over a broad range of wavelengths can be modeled as

$$\epsilon_{DL}(\omega) = \epsilon_{\infty} + \sum_{m=0}^{P} \frac{\omega_{pm}^2}{\omega_m^2 - \omega^2 + i\omega \Gamma_m}. \quad (1)$$

We fit the permittivity of gold to experimentally measured values\cite{3} using a one-pole ($P = 1$) and a three-poles ($P = 3$) model for wavelengths between 650nm and 1200nm. For each pole, $\omega_{pm}$ and $\omega_m$ are used to fit the real part of $\epsilon_{DL}(\omega)$ and $\Gamma_m$ to fit the imaginary part of $\epsilon_{DL}(\omega)$. The \textit{nonlinear least squares method}\cite{4} is used as the fitting method using uniform weights and functions readily implemented in \textit{Matlab}\textsuperscript{TM}. The fits are shown in Fig. 1. The three-poles model shows an error of less than 3% in absolute value over the entire band. In comparison, the one-pole model leads to an error greater than 35% at lower wavelengths, where the absolute value of permittivity is small.

III. FDTD IMPLEMENTATION ON GPU

The FDTD algorithm allows the calculation of propagating electromagnetic waves by alternately calculating the discretized electric and magnetic fields using a first-order spatial and temporal difference equation of Maxwell’s equations\cite{1}. For non-magnetic materials, the electric field update equation

$$\textbf{E}_{n+1} = \frac{1}{\varepsilon} \left( \textbf{E}_{n} - \frac{\Delta t}{\Delta x} \textbf{H}_{n+1} \right).$$

The FDTD algorithm allows the calculation of propagating electromagnetic waves by alternately calculating the discretized electric and magnetic fields using a first-order spatial and temporal difference equation of Maxwell’s equations\cite{1}. For non-magnetic materials, the electric field update equation

$$\textbf{E}_{n+1} = \frac{1}{\varepsilon} \left( \textbf{E}_{n} - \frac{\Delta t}{\Delta x} \textbf{H}_{n+1} \right).$$

We fit the permittivity of gold to experimentally measured values\cite{3} using a one-pole ($P = 1$) and a three-poles ($P = 3$) model for wavelengths between 650nm and 1200nm. For each pole, $\omega_{pm}$ and $\omega_m$ are used to fit the real part of $\epsilon_{DL}(\omega)$ and $\Gamma_m$ to fit the imaginary part of $\epsilon_{DL}(\omega)$. The \textit{nonlinear least squares method}\cite{4} is used as the fitting method using uniform weights and functions readily implemented in \textit{Matlab}\textsuperscript{TM}. The fits are shown in Fig. 1. The three-poles model shows an error of less than 3% in absolute value over the entire band. In comparison, the one-pole model leads to an error greater than 35% at lower wavelengths, where the absolute value of permittivity is small.
in a cell with the permittivity described by Eq. 1 is
\[
E^{n+1} = E_n + C_1 E^n + C_2 \nabla \times H^{n+1/2} \\
+ C_{pml} (\Psi_{E,1}^{n+1} + \Psi_{E,2}^{n+1}) \\
- C_3 E^{n-1} + \frac{1}{2} \sum_{p=1}^{P} \alpha_p J_p^p + \xi_p J_p^{p-1},
\]
where \(n\) denotes the timestep, \(E\) the electric field, \(E_n\) the sourcing term and \(H\) the magnetic field. \(C_{pml}\) is a scaling constant specific to the Perfectly Matched Layer (PML) while \(\Psi_{E,1}^{n+1}\) and \(\Psi_{E,2}^{n+1}\) are recursive accumulators only stored in the PML regions. \(C_1, C_2, C_3, \alpha_p, \xi_p\) are material specific parameters and \(C_3, \alpha_p, \xi_p\) are only used in dispersive materials. Finally, \(J_p^n\) and \(J_p^{p-1}\) denote recursive accumulators only stored for the electric field of dispersive materials. The calculation of \(\Psi^{n+1}_{E,1,2}\) requires \(\Psi^{n}_{E,1,2}\) and \(H\) fields of neighboring cells. In constrast, the calculation of \(J^n_p\) requires \(J_p^n, J_p^{p-1}, E^n\) and \(E^{n-1}\), which are associated to the calculated cell only.

GPU’s typically exploit the Same Instruction Multiple Data (SIMD) computer architecture [5]. This implies that all computation cores execute identical commands on each clock cycle, but on data contained in different memory addresses. To keep track of this process, groups of threads-blocks containing a constant amount of threads are allocated to a kernel which contains the instruction set for each thread. The execution speed of FDTD on GPU’s is often limited by memory bandwidth and latency and thread divergence. The latter occurs when within a kernel, different threads have to perform different instructions, e.g. through an if-statement. Both paths are then performed sequentially, causing significant slowdown [5].

Smart use of memory to minimize bandwidth and latency

To minimize memory transfers, the constant parameters \(C_1, C_2, C_3, \alpha_p, \xi_p\) are stored in a fast read-only texture memory. Also, fast shared memory is used as described in [6], [2], so that the electromagnetic fields in neighboring cells are only loaded once per update. The slower and large device memory is only used to store the fields \(E, H\) and the recursive accumulators for the CPML’s and the dispersive materials.

An additional kernel to alleviate thread divergence

In previous GPU implementations of FDTD [2], the update equations are split into two kernels, one for the electric and one for the magnetic field update equation. However, the electric field update creates a diverging path that leads to slow calculations. The situation is exacerbated for materials with a higher number of poles, as the calculation is done sequentially for the diverging paths. To alleviate this issue, B-CALM separates the electric field update equation into two separate kernels (labeled \(<<\text{Update } E_A>>\) and \(<<\text{Update } E_B>>\) in Eq. 2). The cost per field is one extra read and write operation to device memory to store the intermediate result as both kernels are called sequentially. As the underbraced area is responsible for \(2(P+1)\) read-write operations per field\(^1\), a split kernel is faster as soon as the number of poles \(P > 1\).

IV. RESULTS

We used B-CALM to calculate the absorption efficiency of a metallic sphere of 200nm diameter under plane wave illumination and compare it with Mie theory[7] using the measured values of permittivity[3]. We used a uniform mesh of 11nm and 208x208x400 cells with two symmetry planes and a 15-cell wide PML. We monitor the absorbed power by subtracting the integrated Poynting vector on a closed box surrounding the sphere from the integrated input flux. The simulation computed at 1.4e10cells/min for a three-poles dispersion model on a NVIDIA C-1060 GPU, which is 30 times faster than with Meep[8] on an AMD PhenomTM II X4 945 processor. As shown in figure 2, the single-pole model diverges significantly (error of >50%) while remaining below 5% for the the 3-pole model, greatly enhancing numerical accuracy.

V. CONCLUSION

We show that dispersive materials with complex wavelength dependences can be accurately simulated in a GPU-based FDTD while preserving the speed and low-cost advantage of GPUs. B-CALM, our GPU-accelerated open-source 3D-FDTD simulator allows us to quickly simulate complex metal structures for a broad wavelength range. B-CALM currently supports any user-defined sources, variable grid size, PML and is structured to easily allow the implementation of nonlinearity and anisotropy. B-CALM and its user-friendly interface can be freely downloaded at http://b-calm.sf.net.
